ABSTRACT

Although karst aquifers constitute some of the most important water resources worldwide, generally accepted methods for reliably characterising their hydraulic properties are still elusive. This paper aims at contributing to the discussion by a first-ever attempt to utilise various sets of unique historical data derived from draining a large dolomitic karst aquifer by deep-level gold mines in South Africa. In contrast to conventional pumping tests which only penetrate thick aquifers to a limited extent from surface, this draining took place at the very bottom of the aquifer offering the rare opportunity to capture its entire thickness of nearly a kilometre. The datasets have been treated as analogies to conventional pumping tests applying various types of analytical methods designed for porous media. In order to increase the robustness of the results and to account for specific local conditions a total of four different analytical methods were applied to calculate (horizontal) transmissivity and storage coefficients. The obtained values, in general, compare favourably to previous studies in the area and values reported in literature for similar aquifer types confirming earlier findings that Darcy-based methods can be successfully applied to karst aquifers if the scale of investigation is large enough. Apart from improving the understanding of local karst hydrology the present study also aimed at retrieving and preserving valuable and unique historical datasets that otherwise would have been lost for scientific evaluation and the proactive preparation for mine closure.

Keywords: karst, dewatering, deep level mining, porous medium analytical methods, transmissivity, storage coefficient, Far West Rand

INTRODUCTION

The main purpose of this paper is to explore the usability of historical data gathered over 4 decades of deep-level gold mines dewatering an overlying dolomitic karst aquifer in the Far West Rand (FWR), South Africa, in order to determine hydrological parameters. Based on the conceptual understanding that the set-up under which these data were generated resembles an ultra-large pumping test covering the thickness of the entire karst aquifer, standard analytical methods typically used in pumping tests were applied.

At the same time the study attempts to preserve large sets of unique data that are regarded as most valuable for predicting hydraulic conditions after future mine closure. The latter is particularly important as mining-induced modifications of the natural hydrogeological setting in the FWR will, in all likelihood, have profound impacts on post-mining land use as well as on the long-term availability of surface and groundwater resources.

Hydrogeological conditions of the study area

Geological setting

The karstified dolomites of the FWR goldfield, southwest of Johannesburg, host some of the largest groundwater resources

in South Africa, as well as a range of strong associated karst springs. Gold-bearing reefs below the dolomite have been subject to extensive deep-level mining for many decades. Following a sudden and nearly catastrophic inrush of dolomitic groundwater to the Driefontein Mine in October 1968, it was found necessary to dewater the dolomitic aquifer above the mine void. Owing to the large-scale lowering of the regional groundwater table many of the karst springs dried up. Simultaneously, large quantities of hydrologic data were recorded, some of which are used in this study. The historical and hydrogeological context of the latter data is briefly outlined in this section.

The overall geological situation is depicted in Fig. 1, indicating a north to south cross-section in the FWR as well as the associated stratigraphy.

The dolomite is subdivided into several so called 'groundwater compartments' by approximately north to south-trending intrusive, nearly-vertical dykes, which act as groundwater flow barriers (De Kock, 1964; Brink, 1979). Compartments in the area concerned are the Venterspost, Bank, Oberholzer and, lastly, Boskop-Turffontein Compartments. Data analysed in this study exclusively refer to the Bank Compartment. The northern aquifer boundary is set by granites of the Hartebeesfontein Anticline (Fig. 1). To the south a gradual boundary forms where rocks of the Pretoria Group increasingly overlie the dolomite, preventing pronounced karstification through shielding the underlying dolomite from infiltrating rainfall (Enslin and Kriel, 1968; Brink, 1979). According to Swart et al. (2003), the shielding effect creates a boundary where the thickness of the Pretoria Rocks is at least 150 m. The Ventersdorp Supergroup Lava and Witwatersrand Supergroup Quartzites do not store significant volumes of groundwater

(De Kock, 1964), and therefore constitute the lower flow boundary of the overlying dolomite. The storativity and transmissivity of the dolomites decrease with depth. Figure 3 depicts the vertical zonation provided by Morgan and Brink (1984) and zones of storativity as listed by Winde et al. (2006).

The zone just below the original water table (OWT) extends to a depth of about 70–90 m below surface (mbs) and has a thickness of up to 50 m. It consists mainly of the residues of leached and highly weathered dolomite (wad) as well as of chert and insoluble residues. Owing to the fine-grained nature of wad and the other sediments this zone resembles a porous layer. Below this zone water is stored in a network of large cavities, solution conduits and solution-widened fractures. This zone of ‘cavernous dolomite’ extends to depth of maximal 200 mbs. This is followed by a zone of weakly weathered to solid dolomite with intersecting vertical tectonic faults, joints and fractures that may in cases be widened by solution (Morgan and Brink, 1984). Based on estimates from various authors, Winde et al. (2006) identified 3 zones of storativity, as shown in Fig. 3. In accordance with the storativity of the various zones, the total volume of groundwater stored in the Bank Compartment has been estimated to be between 663 (derived from Winde et al., 2006) and 2 200 Mm³ (million m³) (Schwartz and Midgley, 1975). Values for the transmissivity of the dolomite differ within a broad range, which is typical for karst. Values between 1 000 and 25 000 m²/d have been recorded (Enslin and Kriel, 1959; Schwartz and Midgley, 1975; Bredenkamp et al., 1991).

Dewatering of the Bank Compartment

Dewatering of the Bank Compartment was implemented by West-Driefontein Mine from June 1969 onwards, after a hazardous inrush in October 1968, which occurred after mining operations encountered a major fault, namely, the so-called

Figure 4
3D-model (created with ArcMap®) showing the water table surface (vertically exaggerated) and groundwater drawdown contours (in meters below the OWT) of the Bank Compartment in May 1971 (based on a scanned image of a drawdown contour map (Geological Survey of South Africa, undated). Blue lines mark the outcrop area of dolomitic formations (e.g. Oak Tree) indicating the influence of different hydraulic properties of the formations on the shape of the depression cone. Black dots mark the position and code of boreholes used in this study.

‘Big Boy fault’ (Swart et al., 2003a). In this context the term ‘dewatering’ refers to the process of pumping ingress water from the mine void to surface and then discharging it outside the compartment boundaries at a rate that exceeds the natural groundwater recharge rate (Wolmarans, 1982). This results in gradual lowering of the water table reducing the water pressure above the mine void and thus the associated ingress volume. Dewatering is completed when the falling water table reaches a level at which the ingress rate equals the rate of the natural recharge of that particular compartment. Although the water table is lowered by several hundreds of meters in places,

the compartment is not ‘dewatered’ in the true sense of the word but still contains significant volumes of groundwater (Wolmarans, 1982).

Most of the active drawdown of the groundwater table, which as a matter of policy commenced soon after the inrush, had been completed by 1974. By then the sustained groundwater abstraction through the former inrush point had created a steep depression cone in the south-western corner of the Bank Compartment (Fig. 4). Swart et al. (2003) estimate that about 90% of all water pumped by West- and East Driefontein together still enters the mine void via the Big Boy fault.

Figure 5
Example of a typical source of historical pumping data used in this study.

Characterisation of the used historical data

The data used in this study consist of a variety of formats including diagrams, unpublished reports, maps at various scales, formats and age, pumping and drilling data from mine operators and water-level observations that were scattered over a multitude of sources including private collections, archives, mining companies, governmental departments, and academic institutions (Fig. 5). The data had been collected over decades by Professor EJ Stoch (Mine Water Research Group, North-West University), who prevented many of them from being irretrievably lost.

After retrieving the original data, most had to be converted manually into usable electronic formats for their subsequent compilation and collation in a dedicated database. Given the large amounts of funds spent at the time on generating these datasets and their uniqueness in terms of the scale and nature of associated events, which can never be repeated, their preservation was deemed imperative. Apart from possibly contributing to an improved understanding of karst hydrology in general, these data are also regarded to be of crucial importance for the proactive preparation for future mine closure in the FWR, as the largest and by far most water-rich active goldfield in South Africa. Preserving the data for future scientific use also counteracts the widespread 'loss of institutional memory' in South Africa where changing structures in Government as well as the mining industry often result in the loss of existing data, information, knowledge and expertise (Stoch and Winde, 2010).

This paper focuses exclusively on drawdown data and pumping figures associated with the Bank Compartment (Fig. 2). The total dataset can be subdivided into 3 distinctly different datasets which are briefly characterised.

- **Dataset 1 ('drawdown dewatering')** originates from the dewatering of the Bank Compartment from 1969 to 1974,

Figure 6
Development of the water level in the Bank Compartment and the pumping rate of West-Driefontein during active (drawdown) dewatering.

when the water table was actively lowered by mines pumping out up to 4 times more water than what naturally could be replenished. The pumping rate of West-Driefontein Mine that dewatered the compartment at the time is shown in Fig. 6. Also shown are drawdown observations as available for a total of 66 boreholes located in the Bank Compartment, mostly drilled by the gold mines for this specific purpose. For reasons discussed later, this study uses only observations from 14 boreholes within a distinct radius from the centre of the depression cone and a time period of 24 months, as listed in the Appendix. The geographical location of the used boreholes is shown in Figs 2 and 4.

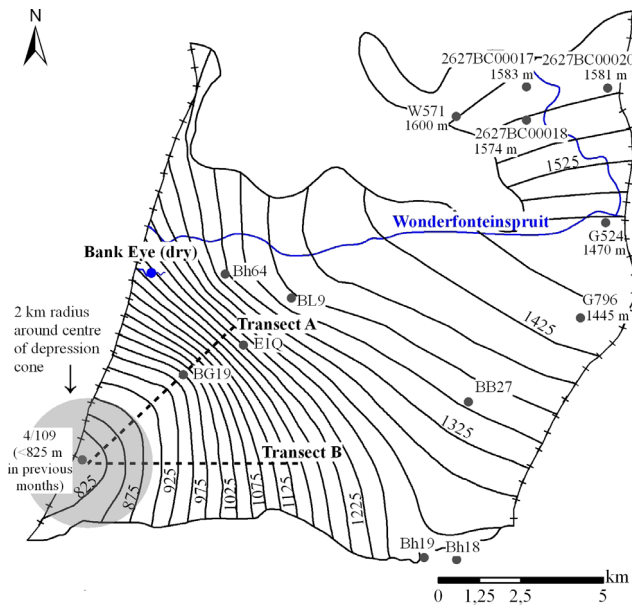

Figure 7

Groundwater contour map of the Bank Compartment in June 1996 (Based on data from Gold Fields Ltd, undated; DWA, 2014). Values of maximum drawdown (s_m) as well as the distance to the centre of the depression cone were derived from the intersected water level contour lines along the two transects A and B.

- Dataset 2 ('inrush event')** originates from the accidental inrush of large volumes of dolomitic groundwater into the West-Driefontein Mine over a period of 4 weeks in October–November 1968. The event caused a water-level drawdown of up to 50 m in places, which was monitored by the mine in a total of 15 boreholes and led to the temporary drying up of the Bank Eye within a few days after the inrush started. This study uses drawdown data from 8 boreholes within the defined radius from the centre of the depression cone (see Appendix). The inrush volume was estimated at between 228 and 386 Mℓ/d (Anonymous, 2005, cited in Winde et al., 2006; Enslin et al., 1977). The latter volume, estimated 3 days after the beginning of the event (quoted in Cousens and Garrett, 1969) appears to be the most cited and more reliable one and is thus used in this study.

- Dataset 3 ('steady-state dewatering')** consists of a snapshot of water-level data for the dewatered Bank Compartment from June 1996, representing the prevailing conditions after the active drawdown of the water table was achieved. Water level data (see Appendix) were digitised from the groundwater contour map shown in Fig. 7.

The data represent quasi steady-state conditions of the aquifer, which is characterised by a stable water table that is maintained by a constant pumping rate. Table 1 gives a condensed overview on the characteristics of the three datasets.

Pumping tests as an analogy to analyse historical data

As can be seen in Fig. 8, the hydrologic setting during dewatering of the Bank Compartment was very similar to a common pumping test setting except that the associated drawdown is much larger than commonly achieved.

The pumping well in the Bank Compartment is represented by the Big Boy fault, which in the following is called 'inrush point' (approx. coordinates: 27.477774, -26.361681; Fig. 8). Thus the above situation resembles an ultra-large pumping test, which allows the application of generalised analytical methods developed for pumping test analysis. Descriptions of these methods can, amongst others, be found in McWhorter and Sunada (1977) or Langguth and Voigt (2004).

Selecting appropriate analytical methods for the Bank Compartment

The first analytical method for the evaluation of (transient) pumping test data was developed by Theis (1935) for an aquifer with very specific conditions, as listed in Table 2. Today a wide range of those analytical methods exist, each applying to very specific aquifer conditions. Table 2 lists the methods applied in this study including required aquifer conditions in relation to conditions found in the Bank Compartment.

Given the large scale of the karst aquifer investigated in this study, it was found appropriate to apply porous-media analytical methods. While applying simple analytical methods comes with a number of limitations, this was regarded as acceptable given that the study aims at a first evaluation of the aquifer rather than developing a comprehensive (numerical) model. Consequently, 3 different porous-media analytical methods were applied as well as the analytical software tool MLU for

Dataset	Cause of water level drop	Period	Duration	No. of boreholes (total/used)	Range of water levels*	Corresponding zones of karstification (Fig.3)**	No. of water level data points	Ave. pumping rates (Mℓ/d)
1	Active dewatering	27.08.1969 – 28.07.1971	24 months	66/ 14	0.5–194.2	Weakly weathered to solid (>200 mbs to inrush point at 863 mbs*)	161	252 (75–341)
2	Accidental inrush	26.10.1968 – 23.11.1968	4 weeks	15/ 8	0–43.59	All zones (elevation of original water table to inrush point at 863 mbs)	120	386
3	Steady-state dewatering	26.06.1996	1 day	unknown	278–603	mostly solid dolomite (>600 mbs to inrush point at 863 mbs)	25 (14: Transect A, 11: Transect B)	61

* in meters below original water table

** refers to the thickness of the water-saturated rock column at the end of the drawdown below the maximum water level depth recorded (mbs = meters below surface)

Windows (Hemker and Post, 2012).

Treating the aquifer like a homogeneous porous medium is based on the assumption that the large area considered here represents a representative elementary volume (REV). The REV is defined as the smallest volume over which microscopic fluctuating parameters can be statistically meaningfully described by averaged parameters representative of the whole (Bear, 1972), i.e., that over a certain volume an average hydraulic

conductivity can be determined that adequately describes the flow discharged from the block, despite the fact that the microscopic (local) hydraulic conductivity fluctuates within the block (due to different porosity types, i.e., porous matrix, fracture and conduit porosity).

Even though the aquifer shows characteristics of all major aquifer types (porous, fractured and karst), analytical methods for double-porosity (for fractured rocks) were deliberately

Figure 9
Diagrams showing data curves of drawdown (s) plotted against time/radius² (t/r^2) (r =distance from the observation well to the pumping well) for Datasets 1 and 2. The red line represents the Theis type curve (dimensionless drawdown $W(u)$ against the dimensionless time parameter $1/u$).

ignored since assumptions underlying those methods hardly comply with the complex geological setting found in the Bank Compartment. Moreover, the application of double porosity methods is more complex and often requires rather detailed hydrogeological information that is not always available. The unusual drawdown curves as well as the uncertainty associated with the gathering of the data – this refers, for example, to the constantly changing pumping rate, dewatering of fractures and the fact that measurements in boreholes only started some time after the abstraction of water commenced – render the application of double-porosity methods problematic (e.g., obtaining a unique fit of drawdown and type curves) and would even hamper the interpretation of results by adding further vagueness.

In order to reduce the interference by double-porosity effects, this study considers only observation boreholes with a large distance ($>2\ 000$ m) from the intrush point. This is based on findings of Bourdet and Gringarten (1980), indicating that double-porosity effects are confined to a limited area surrounding the pumping well and can be neglected outside this area where drawdown is described by the type-curve of Theis. The above distance was determined from carefully observing drawdown data as well as preliminary calculations showing that boreholes closer to the intrush point are characterised by different drawdown behaviour.

For this particular case, a further advantage of porous-media analytical methods over double-porosity methods exists, as they allow for considering no-flow boundaries present in the aquifer (i.e. Bank Dyke). The analytical methods used in the study were that of Thiem (1906), Theis (1935) and Stallman (as quoted in Ferris et al., 1962) together with the software tool MLU (multi-layer unsteady state) for Windows (Hemker and Post, 2012).

The rather rigid requirements of the Theis methods are listed in Table 2. All other methods used here are, in essence, variations of the Theis method that try to overcome some of the limitations by introducing certain modifications. The Stallman method, for example, can be used if the depression cone reaches one or more aquifer boundaries, as is the case in the Bank Compartment (Fig. 4). The Thiem method, on the other hand, only applies to steady-state groundwater flow conditions in a pumped aquifer and is therefore limited to Dataset 3. MLU for Windows is a software tool for calculating drawdowns and analysing pumping test data. It combines an analytical solution

technique with numeric applications (Stehfest's numerical method), the superposition principle and the Levenberg-Marquardt algorithm. Detailed information on the theoretical background is given by Hemker and Maas (1987) and Hemker (1999). Like other analytical methods, MLU assumes simplified aquifer conditions such as homogeneity, isotropy and the infinite horizontal extent of the aquifer (Carlson and Randall, 2012). However, despite making these assumptions MLU allows for analysing more complex aquifer conditions than the other methods applied in this study. For the case study at hand this is of particular importance as MLU is able to account for the variable pumping rate that affects the largest of the three datasets (Dataset 1, Fig. 6). All other analytical methods theoretically require at least a couple of drawdown observations during a period of stable pumping. MLU can also consider the influence of aquifer boundaries on the drawdown observations (as does the Stallman method) and thus considers the hydrogeologic setting more adequately, compared to the other methods used in this study.

Application of the selected analytical methods

Owing to the large drawdown observed in Datasets 1 and 3, the saturated thickness of the aquifer is significantly reduced, which creates unconfined (phreatic) water table conditions. However, the analytical methods applied require confined aquifer conditions. To overcome this obstacle the observed drawdown data had been adjusted by transferring values of observed drawdown (s) into the so-called corrected drawdown (s') data using the method of Jacob (1963).

The analytical methods applied in this study are well-established standard methods for analysing pumping test data. Therefore the technical details are only briefly touched on. For more information the original literature may be consulted (e.g. Theis, 1935; Kruseman and De Ridder, 1991).

Theis method

Drawdown curves of Datasets 1 and 2 as well as the Theis type curve are depicted in Fig. 9. Each data curve was brought to match with the type curve by shifting the curves parallel to the axes as illustrated in Fig. 10.

Following the advice of Kruseman and De Ridder (1991), more weight was given to data gathered towards the end of the

Figure 10

The drawdown curve of Borehole E1N (data curve) is brought to match with the Theis type curve (dotted line)

pumping test while matching both curves. According to the authors the late-time data (Dataset 1) would reflect the combined fracture and matrix system and can be described by the Theis equation. The curves at early times show a deviation of the data from the Theis model, which is likely to be due to the ignoring of double porosity effects.

A match point was chosen, and corresponding values for $W(u)$, $1/u$, t/r^2 and s were read from the axis. These values were inserted into the Theis equation ($T = \frac{Q}{4\pi S} \cdot W(u)$ and $S = \frac{4Tt}{r^2} \cdot u$) in order to calculate the transmissivity (T) and the storage coefficient (S). The calculation also requires the pumping rate (Q) at which the aquifer was pumped during the observed drawdown. In Dataset 1 the aquifer was pumped at a variable rate that cannot be accommodated in the Theis equation. Therefore an average pumping rate over the 24-month observation period had to be calculated (252 Ml/d). For Dataset 2 the pumping volume was 386 Ml/d.

Stallman method

The Stallman method (first quoted in Ferris et al., 1962) is used in the case when a pumping test is conducted close to an aquifer boundary. In such cases the assumption of the Theis method, i.e., the infinite extent of the aquifer, is no longer valid

Figure 12

Observed and calculated drawdown for Borehole E1N (Dataset 1) as obtained from MLU

and the drawdown in the observation boreholes will be different from the drawdown that would occur in an (seemingly) infinite aquifer. In order to account for the resulting difference, the Stallman solution uses modified type curves while still employing the principle of curve matching (superposition). The method is based on the theory of 'image wells' described by Ferris (1959). The theory replaces the bounded aquifer with one pumping well by assuming a hypothetical infinite aquifer that is pumped at 2 wells as explained for Fig. 11.

MLU for Windows

As a third method, MLU for Windows was applied to Datasets 1 and 2. For detailed information on the mode of operation of MLU the reader is referred to the software manual (i.e., Hemker and Post, 2012). The aquifer was treated as a single-layered aquifer of 810 m thickness. Each observation borehole was evaluated separately. An image well was set in order to account for the Bank dyke as no-flow boundary. MLU requires initial estimates for transmissivity and the storage coefficient. For that purpose values calculated from the Theis method were used. MLU was set to estimate both parameters, i.e., transmissivity and the storage coefficient, simultaneously. In order to optimise both parameters, MLU calculates the drawdown curve that fits the observed drawdown curve the best. Figure 12 displays the curve of calculated and observed drawdown of Borehole E1N (Dataset 1) as an example. Similar results were obtained for other boreholes. Figure 12 shows a good fit of observed and calculated values except for early time drawdown, which shows that the aquifer behaviour at early times differs from the model presumed by MLU.

Figure 11

Section illustrating the theory of image wells for an aquifer with one no-flow boundary. Instead of a bounded aquifer system with 1 pumping well (real well) the theory assumes a hypothetical aquifer of infinite extent that is pumped at 2 wells (adapted from Ferris et al., 1962). It was decided to only consider the Bank Dyke as a no-flow boundary, and not the southern edge of the dolomite outcrop area as was done previously by Schwartz and Midgley (1975). This is mainly because drawdown contours in Fig. 4 indicate that the southern edge did not truly act as a no-flow boundary since groundwater contours would otherwise intersect the boundary of outcropping dolomite at right angles.

Figure 13

Semi-logarithmic plots of the corrected maximum drawdown (s_m') against the distance to the centre of the depression cone. Black dots indicate data of corrected maximum drawdown (s_m') measured along Transects A and B in Fig. 7.

Thiem method

The Thiem (1906) method was used to evaluate Dataset 3. It uses values of maximum drawdown (s_m') measured at different distances from the centre of the depression cone to calculate the transmissivity. The pumping rate that maintained the depression cone was 61 Mℓ/d. Measurements of maximum drawdown were made in 2 directions to representatively cover the aquifer (Transects A and B, Fig. 7). Obtained values of maximum drawdown are listed in the Appendix (Dataset 3).

For both transects (A and B), values of corrected drawdown s_m' are plotted against the corresponding distance (log-scale) to the centre of the depression cone (Fig. 13).

Then the best-fitting linear regression line and the slope Δs_m (maximum drawdown difference per one logarithmic unit of distance) are determined. The deviation of the observed drawdown from the regression line shows that drawdown towards the centre of the depression cone differs from what the method predicts for a homogeneous and porous aquifer. A reason for this could be that a vertical flow component increasingly impacts on the drawdown with decreasing distance to the inrush point. Therefore the values close to the inrush point were ignored while adjusting the best-fitting linear regression line.

Finally the Thiem equation ($Q = \frac{2\pi \cdot T}{2.30} \cdot \Delta s_m$) is used to calculate the transmissivity. It is not possible to determine the storage coefficient from the Thiem method.

RESULTS AND DISCUSSION

Values of transmissivity and storage coefficients as derived from the four analytical methods are listed in Table 3.

Table 4 provides a condensed overview of the obtained T- and S-values for each analytical method and the associated dataset.

Values of transmissivity of individual boreholes show a high variability (relative standard deviation (SD) around 50%), which one would expect for a karstified aquifer. This indicates that the REV-concept is only applicable to a certain degree as expanding the investigated area (or adding additional observation boreholes) could significantly change the obtained average value. On the other hand, the fluctuations are small enough for deriving an order of magnitude for the transmissivity.

Sizable differences also exist between the results of the various analytical methods within a particular dataset.

For Dataset 1, transmissivities from the Theis and Stallman method are significantly lower than those for MLU. This difference is most probably attributable to the fact that both analytical methods (Theis and Stallman) do not consider the variable pumping rate, which affects Dataset 1 (Fig. 6). In contrast, in Dataset 2 the aquifer was pumped at a stable rate. Hence, values for the Stallman method differ only slightly from MLU. However, the average transmissivity received by the Theis method is still considerably below that of MLU. This is because MLU considers the influence of the no-flow boundary, i.e., the Bank Dyke, which the Theis method does not. Therefore, it is believed that for Dataset 1 MLU yields the most reliable results, while for Dataset 2 this is true for MLU and the Stallman method.

Results of transmissivity derived from inrush data (2 468 m²/d) are, on average, one order of magnitude higher than the dewatering data (285 m²/d). One possible explanation for this significant difference is that the two datasets represent very different thicknesses of water-filled (saturated) dolomite. The much higher T-value (2 468 m²/d) was derived from the completely water-filled aquifer, with all vertical zones of the dolomite being saturated (Fig. 3). In contrast, the 10-times lower transmissivity (285 m²/d) only represents the aquifer after the upper ~200 m below the OWT have already been dewatered. Therefore this value reflects only the zone of 'fractured and solid dolomite and does not consider the highly transmissive zone above it. In principle this is also true for the transmissivity obtained from the Thiem method. But since the latter does not take into account the no-flow boundary it is not considered in the following interpretation. Figure 14 summarises the calculated average values of hydraulic conductivity in relation to corresponding zones of karstification and storativity.

Values of hydraulic conductivity calculated for individual boreholes range from $7.0 \cdot 10^{-5}$ to $3.1 \cdot 10^{-4}$ m/s for the upper 200 m. For greater depths, values range from $2.9 \cdot 10^{-6}$ to $1.0 \cdot 10^{-5}$ m/s (Table 3). Figure 15 displays ranges of hydraulic conductivity in relation to values found in literature for similar aquifers.

It can be seen that values from >200 m below the OWT concur with weakly fractured to solid dolomite. Values from above 200 m comply with moderately fractured to cavernous carbonate rocks. Thus values are in general agreement with what one would expect for the respective zones. The transmissivity of 2 468 m²/d calculated in this study is consistent with the value of 2 983 m²/d that Enslin and Kriel (1959) obtained

TABLE 3
Transmissivity (T) and the storage coefficient (S) calculated from the drawdown measured in boreholes in the Bank Compartment. Listed are results for 4 different analytical methods that were applied to 3 datasets

for the similar nearby compartments (using an unspecified method), and the value of 1 818 m²/d that Bredenkamp (1991) obtained for the nearby Gemsbokfontein Compartment using the double-porosity model of Boulton and Streltsova (1977). Thus indications are that results of MLU and the Stallman method (in Dataset 2) have a realistic order of magnitude. To a certain degree this supports the argument that realistic results can be obtained from applying porous-media analytical

methods to non-porous aquifers, provided the spatial scale of investigation is large enough (i.e., not considering a single karst channel or fracture, for example, but a large network of interconnected conduits with varying transmissivities). This, however, should not be seen as proof that those methods are in general applicable to all karst aquifers, given the deviation between the theoretical model of porous-media methods and the actual hydrogeologic situation as discussed in the section above.

Figure 14
Calculated values for transmissivity (T) and hydraulic conductivity (k_f) in relation to previously identified vertical zones of karstification and porosity.

Less reliable, however, are the calculated storage coefficients. Not much weight at all should be given to the storage coefficients obtained from Dataset 1 as these values display a so-called 'distance-dependency', as illustrated in double-logarithmic plots (Fig. 16).

The plots show that the storage coefficient of individual boreholes increases with decreasing distance of the borehole to the pumping well (here: inrush point). This phenomenon was first recognised in South Africa by Bredenkamp et al. (1991), applying different analytical methods to a similar dolomitic aquifer. Later the same distance-dependency of storativity values was found in numerous fractured and karst aquifers throughout South Africa (Kirchner and Van Tonder, 1995). A possible explanation provided in literature is related to the concept of double-porosity. Porous-media analytical methods do not consider that the groundwater flow in fractured/karst aquifers is governed by different pressure gradients that develop between large fractures/conduits and the pore-matrix/small fractures during drawdown. The generated pressure gradients are larger in close proximity to the pumping well and decrease with increasing distance, possibly explaining the distance-dependency of the associated storage coefficients (Neuman, 1994, personal communication quoted in Kirchner and Van Tonder, 1995). The problem of distance-dependency, however, is not restricted to porous-media analytical methods, as Van Tonder et al. (2002) showed that it also appears when applying double-porosity analytical methods that claim to account for the very double-porosity effects that are thought to cause the dependency.

For some reason the distance-dependency of the storage coefficient does not appear in values for Dataset 2 (Fig. 16), which warrants an interpretation. An average value of 0.0067 is derived from MLU and the Stallman method. This equals a storativity of 0.67 % (uniform over the entire thickness). Values

¹ calculated from MLU-transmissivities, ²Freeze & Cerry (1979), ³Domenico & Schwartz (1990), ⁴Heath (1983)

Figure 15
Values of hydraulic conductivity for carbonate and karstified rock types. Also shown are values of hydraulic conductivity calculated for different depths of the Bank Compartment. Vertical bars represent average values.

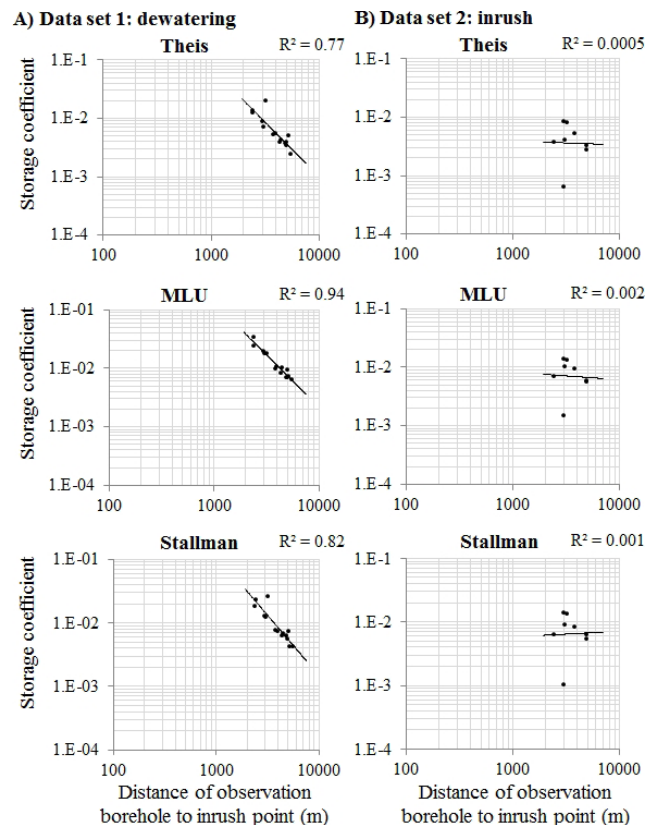

Figure 16
Log-log plots of the storage coefficient of selected observation boreholes against distance of the observation borehole to the inrush point (for Datasets 1 and 2).

of storativity for different zones quoted in Fig. 14 average to 0.5% if the dolomite is treated like a homogenous unit. Thus the value derived from MLU and Stallman is in the same order of magnitude as previous estimates even though it does not consider vertical changes in storativity.

Estimating the total volume of water stored in the dolomite of the Bank Compartment based on a porosity of 0.67% results

in some 923 Mm³. (For this estimation the dolomite aquifer was assumed to extend approx. 1 070 m south of the southern border of the dolomite outcrop area, where the Pretoria Group rocks (dipping approx. 8°) reach a thickness of 150 m. This results in an areal extent of some 170 Mm². The average depth of the dolomite was assumed to be 810 m. By this means the volume of the dolomite was estimated at 1.38*10⁺¹¹ m³.) This falls between previous estimates for the Bank Compartment ranging from 663 Mm³ (following from Winde et al., 2006) to 2 200 Mm³ (Schwarz and Midgley, 1975), with Brink (1975) suggesting that the latter value probably represents an overestimation.

SUMMARY AND CONCLUSIONS

In the course of several decades of deep-level gold mining in the FWR, significant amounts of hydrogeological data were gathered relating to accidental as well as deliberate draining of a large overlying and highly karstified dolomitic aquifer.

Given the uniqueness of the situation, where an over 800 m-thick aquifer was dewatered literally by 'pulling the plug' at its very bottom – something only possible for deep-level mining operations – and the spatial and temporal scale of related events, it was deemed to be of scientific importance to preserve the associated data and prevent their irretrievable loss through diligent compilation in a dedicated database where they are available to scientists for further evaluation.

In total, 3 different datasets are analysed, all consisting of weekly to monthly groundwater-level measurements and associated daily pumping volumes that were generated during an accidental inrush event into the deep-level mine void and the subsequent dewatering of the overlying karst aquifer over the next 40+ years.

This paper is a first-ever attempt to use these data for characterising the hydraulic properties of the drained Bank aquifer, hoping that the unique situation and extreme scale of the associated events will provide new aspects for understanding the still challenging hydrology of karst aquifers in South Africa and perhaps even worldwide.

In applying the analogy of a pumping test, the 3 datasets were analysed by 4 porous-media –based analytical methods, differing mainly in the degree to which they are able to account for local conditions.

The obtained results are generally in good agreement with each other (exceptions are explained) as well as with previous estimates for the study area and values reported in general literature for similar rocks types. This is interpreted as confirming earlier suggestions that porous-medium analytical methods can indeed be applied to karst aquifers provided the spatial scale of investigation is large enough.

The study also shows that the accuracy of the obtained values was less affected by the fact that the applied analytical methods were actually developed for porous media and more by the degree to which the various requirements of the applied methods (such as constant pumping rates, no-flow boundaries, etc.) were met. Not surprisingly, MLU, as the one method that took most of the local peculiarities into account, yielded the best-fitting results for the largest of the three datasets.

The most pronounced limitations of the applied methods came from the fact that they all ignored vertical variations in permeability of the dolomite. This was revealed by comparing 2 different datasets pertaining to different vertical zones of the dolomitic column. The fact that the highly permeable zones in the dolomite were covered in one dataset, but not in the other,

resulted in the respective transmissivity values differing by an order of magnitude. This, in turn, allowed for the first time quantification of the transmissivity of the different vertical zones of the dolomite in the Bank Compartment.

While obtained storage coefficients are generally less reliable than transmissivity values, their application yielded reasonable storage volumes that compare favourably with existing data and earlier estimates. However, no satisfactory explanation could be found why distance-dependency of the storage coefficients was observed in one dataset but not in the other. Thus storage values are to be interpreted cautiously.

Based on the obtained parameters, it is envisaged to investigate the effects that mining through dykes below the dolomite has on the future elevation of the recovered water table after mining and the associated dewatering ceases in the area. Given the large costs currently incurred by implementing emergency measures to address effects of haphazard mine closure in the East, Central and West Rand, a more pro-active and coordinated approach to mine closure in the FWR, as the most water-rich of all goldfields in South Africa, is deemed to be imperative.

ACKNOWLEDGEMENTS

The authors gratefully acknowledge the support and contribution of Prof EJ Stoch, who made his unique collection of hydro-logic, historical data available. Special gratitude is owed to Mrs Heather Erasmus for editing. Last, but not least, the authors wish to graciously thank the National Research Foundation (Grant No. 86331) for financial support.
